Abstract

Background: The decline in cardiorespiratory fitness and lung function was higher in smokers. Training method could mitigate some of the negative consequences of smoking among smokers unable or unwilling to quit.

Objective: To examine the effects of continuous training on lungs functional capability and cardiorespiratory fitness in smokers.

Methods: Fifteen cigarette smokers, 14 hookah smokers, and 14 nonsmokers were assigned to low-intensity continuous training (20-30 minutes of running at 40% of maximum oxygen uptake \(O_2\)max). Lung function and cardiorespiratory fitness parameters were determined using respectively spirometer and treadmill maximal exercise test.

Results: Continuous training improved forced expiratory volume in one second (FEV1) and forced expiratory flow at 50% of FVC (FEF50 %) in all participants, smokers and nonsmokers (p < 0.05). In contrast, forced vital capacity (FVC) improvement was significant only among cigarette smokers (CS) (+1.7±2.21%, p < 0.01) and hookah smokers (HS) (+1.3±1.7 %, p < 0.05). Likewise, an improvement in cardiorespiratory fitness in both smokers groups without significant changes in diastolic blood pressure (DBP) for CS group and in velocity at maximum oxygen uptake (vO2max) for HS group.

Conclusion: The low-intensity continuous training improves cardiorespiratory fitness and reduces lung function decline in both cigarette and hookah smokers. It seems to be beneficial in the prevention programs of hypertension. It could have important implications in prevention and treatment programs in smokers unable or unwilling to quit.

Keywords: Cigarette smokers; hookah smokers; pulmonary function; cardiorespiratory fitness; continuous training

DOI: http://dx.doi.org/10.4314/ahs.v15i4.16

Introduction

The decline in fitness and lung function was significantly higher in smokers than in nonsmokers and could not be explained by differences in age and physical activity.

Smoking is the biggest risk factor involved in the decline of lung function. In this context, several authors have found that smoking reduces the forced expiratory volume in one second (FEV1), forced vital capacity (FVC) and Tiffeneau index (FEV1/FVC) in both sexes. Smoking the cigarettes or hookah consumption has risks of addiction, illness or death. Koubaa et al. assessed the harmful effects of hookah consumption compared to cigarette smokers in sedentary adult’s subjects by measuring biochemical and cardiorespiratory parameters. This study reinforces the evidence that hookah consumption was associated with exposure to toxic sub-
stances and harmful effects on cardiopulmonary function and antioxidant defense capacity and produced in some cases, the same effects as the cigarettes. Many previous studies suggest that smoking hookah has adverse effects similar to cigarettes. The findings of Saetta et al. indicate that cigarette smoke affects not only the airways, but also the lung parenchyma and pulmonary arteries, causing irreversible obstruction of the branches. The main risk factor for this obstruction is smoking. Thus, and according to a Swedish study that was interested in subjects aged over 76 years, nearly 66.7% of smokers presented with a chronic obstructive pulmonary disease (COPD). This data suggests that COPD is a disease that affects the majority of smokers when they live long enough. This pathology, according to WHO statistics, is the cause of death that will increase more in industrialized countries and will become the third leading cause of death in 2020. In Tunisia, the death rate from smoking-related COPD is 84% in men and 35% in women.

Undoubtedly, the inhalation of cigarette or hookah smoke is associated with hypertension (HT), an increase in resting heart rate (HR) and at exercise and a decreased tolerance to the effort. These effects are important firstly via the nicotine which causes an increase in myocardial oxygen demand and, secondly, by the functional anemia induced by the increased uptake of carbon monoxide on the hemoglobin. Therefore an increased tachycardia, decreased maximal oxygen consumption and harmful effect on peripheral muscle with early anaerobic threshold. These different effects result in reduced of effort tolerance. We would like discover a physical activity method to become a strategy so that it can improve cardiopulmonary performance and delay the lung function decline caused by smoking.

In order to prevent and slow the progression of hypertension and improve health and cardiorespiratory performance, several previous studies have suggested that physical activity can play a central role. In this context, the Canadian medical association indicated that regular moderate physical activity (40% to 60% of $O_2\text{max}$) for 50 to 60 minutes, 3-4 times a week was recommended in the prevention or treatment of hypertension. Fagard et al. confirm these results, showing a significant reduction in systolic blood pressure (SBP) and diastolic blood pressure (DBP) for a repeated exercise 3-5 times per week for 30 to 60 min and 40% to 50% of $O_2\text{max}$. In addition, other studies using different training periods showed significant improvements in $O_2\text{max}$ and in the rate of spontaneous walking and a significant decrease in fatigue, and an improvement of physical ability and life quality.

Exercise may have the potential to mitigate some of the negative consequences of smoking. Some studies suggest that training at vigorous exercise intensity (60-85% of reserve heart rate) can be a useful aid to stop smoking. To our knowledge there’s lack of empirical evidence documented that such a method of physical activity has beneficial effects on physiological symptoms of smokers. Therefore, there is a need to expand the range of potentially effective harm reduction strategies among smokers unable or unwilling to quit smoking.

Method
Participants
A total of forty-three sedentary and healthy male smokers and non-smokers from the general community of Tunisia, which belongs to the public function (profession does not require physical exertion), volunteered to participate in this study and were recruited within pharmacology laboratory of the Faculty of Medicine, University of Sfax, Tunisia. The anthropometric characteristics of participant are shown in [Table 1].
Participants were admitted to the training program after approval by a cardiologist physician. They were normolipidemic (fasting triglycerides < 1.7 mmol/L), nonobese. No subject used nutritional supplements or medications. Presence of any kind of disease (based on history, medical examination, and exercise stress testing), or FEV1/FVC% < 70%27,28, or involvement in regular physical activity or exercise program for the 12-month period preceding the visit day, were also exclusion criteria. On the basis of these criteria, 9 subjects from 52 were excluded. Eventually, 43 subjects were included in subsequent tests and they were admitted to the training program.

After receiving a complete verbal description of protocol, risks and benefits of the study, subjects provided written consent to an experimental protocol approved by the Research Ethics Committee of the Faculty of Medicine, University of Sfax, Tunisia. Smokers were instructed to refrain from smoking at least one hour prior to reporting to the laboratory as suggested by Dietrich et al.29

Cigarette and hookah smokers were recruited according to the number of cigarettes and hookah per day and how long they had been smoking. We considered cigarette smokers all subjects with consumption greater or equal to 10 pack-years (PY) and an average score of tobacco dependence of 8.12 ±1.41, measured by the Fagerström nicotine dependence test30. We quantified hookah consumption, as in the study of Kiter et al.31, in hookah- years (HY) and kg of cumulative tobacco. The tobacco used in a single hookah session weighs between 10 and 25 grams32. Regular hookah smokers are those having tobacco consumption greater or equal to 5 hookah- years (HY)33.

Participants were divided into three groups, and they performed a low-intensity continuous training program 3 times a week for 12 weeks. A cigarette smokers group (CS) (n = 15); a hookah smokers group (HS) (n = 14) and another nonsmokers group (NS) (n = 14). All subjects were subjected to a spirometric assessment and physical test session before and after the training program. The session includes lung function and treadmill maximal exercise test. All these measurements were performed by the same examiners to avoid methodological errors.

**Anthropometric measurements**

Body weight was measured to the nearest 100 grams with a calibrated electronic scale (TANITA TBF.350 model), and height was measured to the nearest 1mm with a fixed stadiometer. Body mass index (BMI) was calculated with the formula: [BMI (kg.m⁻²) = Weight (kg) / Height² (m²)].

**Calculation of recovery index**

Heart rate was recorded every minute during 5 minutes after the exercise test. Calculation of recovery index is based on two data: Calculation of the regression index and the correlation index.

Recovery index = Regression index x correlation Index

**Lung function assessments**

A portable spirometer (MIR Spirobank G USB Spirometer, Rome, Italy) was used to assess smokers lung function. Standard procedure requires forced vital capacity (FVC) and forced expiratory volume in one second (FEV₁) and should be measured from a series of at least three forced expiratory curves34. This study required participants to perform three correct manoeuvres. Participants completed the spirometry assessment seated

with a nose clip attached, the mouthpiece is placed into
the mouth, lips and teeth around the mouthpiece to
form a tight seal and breathe out hard and quickly until
all air is expelled.

It is vital that participants inhale completely, to total
lung capacity, and continue to exhale until they have
fully emptied their lungs (to residual volume).
Pulmonary function variables included: FVC, FEV1,
FEV1/FVC ratio, FEF25-75% and FEF50%. Results were
expressed as percentages of the predicted value to al-
low comparison of results across participants.

Physical fitness assessment

\( \dot{V}O_2 \) max and max heart rate measurements during exer-
cise were examined through treadmill maximal exercise
test (COSMED Pulmonary-Function Equipment 37
Via dei Piani di monte Savello I-00040 Rome ITALY).
This dynamic and maximum test, until fatigue, consists
in increasing the speed of 1kmh\(^{-1}\) every 2 min, after
warm up of 5 min with a 6 kmh\(^{-1}\) speed until the par-
ticipant could no longer continue. \( \dot{V}O_2 \) max is reached
when oxygen consumption remains at steady state de-
spite an increase in workload. Heart rate using (Polar
Electro Oy, Kempele, Finland) was monitored through-
out the test and was recorded at the conclusion of every
two-minute stage. The oxygen consumption (\( \dot{V}O_2 \)) was
continually recorded and measured in real time using
oxygen analyzer (Fitmate, version 1.2 PRO COSMED).
At the end of the test a detailed report will be printed.
Verbal encouragement was provided throughout the
test to ensure that the maximal effort was achieved.

Continuous training protocol
Subjects of three groups underwent a continuous train-
ing program during a 3-months period. Training was
performed continuously for 20 minutes (first month),
25 minutes (second month) and 30 minutes (third
month), three times per week at an intensity of 40% of
\( \dot{V}O_2 \) max, on race track of 400 m at the Institute of
Sport of Sfax, Tunisia. The cones placed and spaced 20
meters on a race track. At each beep, the subject must
reach the following cone. All warm-ups before training
should be between 50% and 60% of maximum heart
rate for a period of about 10 minutes.

It was asked of participants to run with a continuous
rhythm respecting sound beeps and the requested time
throughout the training session. The training load was
insured by time and traveled distance and controlled by
sound beeps. (T: the time between two cones; d: dis-

tance between two cones; V: proposed velocity). The
load increase during the training period was provided
by the increase in working time and the distance cov-
ered in each session. All participants successfully com-
pleted the training period and no absences were record-
ed during all sessions. In addition, we have verified that
there was no involvement in physical activity or exercise
program throughout the 12-week training period.

Statistical analysis
All statistical tests were processed using STATISTICA
Software (StatSoft, France). The data was expressed as
mean ± SD (standard deviation). After normality verifi-
cation with the Shapiro-Wilk’s w test, and homogeneity
of variances with Levene’s test, parametric tests were
performed. One-way ANOVA was used to indicate
inter group differences in the baseline subjects’ char-
acteristics. Inter and intra-group comparisons of the
variables were made by two-way ANOVA (group vs.
training) with repeated measurements. Least Significant
Different (LSD) post-hoc analysis was used to identi-
fy significant group differences that were indicated by
one-way and two-way ANOVA. A probability level of
0.05 was selected as the criterion for statistical signifi-
cance.

Results
Before and after training, we did not observe any sig-
ificant difference in body-weight and BMI values be-
tween the nonsmoker and smoker groups (Table 2).

However, most of the spirometric values were higher in all of non-smokers subjects and significantly different to those of cigarette and hookah smokers before our training program. We reported in table 3 the spirometric values in percentages of the predicted value of our entire population before training.

FVC = forced vital capacity; FEV\(_1\) = forced expiratory volume in one second; PEF = peak expiratory flow; FEF\(_{50\%}\) = forced expiratory flow at 50% of FVC; FEF\(_{25-75\%}\) = forced expiratory flow at 25 to 75% of FVC; *, **, *** = significant difference compared with nonsmokers at p < 0.05; p < 0.01; p < 0.001 respectively; # = significant difference compared with cigarettes smokers at p < 0.05.

Compared to nonsmokers group, ANOVA showed significant differences for all measured parameters. For explored values of FVC, PEF and FEF\(_{25-75\%}\), statistical analysis showed no difference among cigarette and hookah smokers.

Application of LSD post-hoc test showed a similar significant difference (p <0.05) in FEV\(_1\), FEV\(_1\)/FVC, and FEF\(_{50\%}\) of CS subjects compared to HS subjects. Furthermore, the FEV\(_1\) of CS group tends to be lower than of NS group, but the difference was not significant. The HS group also showed a low level of FEF\(_{50\%}\) compared to the two groups CS (P < 0.05) and NS (P < 0.01).

**Training effect on lung function**

The improvement rate in the respiratory functional exploration results after the training period, is summarized in table 4.
Table 4. Improvement rate (Δ) of respiratory parameters of the three groups (NS, CS, HS).

</tbody>
</table>

The three-month continuous training period, induces changes in respiratory parameters, however, they vary according to the group. This change did not show significant differences in PEF, FEV1/FVC and FEF 25-75% measured after the training period.

The training period produces an increase in FVC of all our participants; however, this improvement was significant only among smokers. It is of the order of +1.7 ± 2.21% (p < 0.01) for CS group and +1.3 ± 1.7% (p < 0.05) for HS group. In addition, all our subjects benefited a significant increase in FEV1 after the training program (Table 3). Thus, the improvement was +1.83 ± 2.69% of NS group (p < 0.05), +1.9 ± 2.13% (p < 0.05) in CS group and +1.7 ± 2% (p < 0.05) for the HS group. The FEF50% of the three groups NS, CS and HS follows the same trend as the FEV1, with significant differences (p < 0.05), representing increases of +1.08 ± 2.19%, +1 ± 2.36% and +1.6 ± 2.5%, respectively.

Training effect on cardiorespiratory fitness
The results of maximal exercise test of the three groups before training period are summarized in table 5.
The (LSD) post-hoc test showed that the two groups CS and HS had resting HR, SBP and DBP similar and significantly higher than those of nonsmokers (p < 0.001). Similarly, no significant difference in these values was revealed between the two smoker groups.

Regarding the $\dot{V}O_2$max, $\dot{V}O_2$max and recovery index, the statistical analysis showed significant differences between the two smoking groups (p < 0.001, p < 0.001 and p < 0.01, respectively). Similarly, we have registered in the values of $\dot{V}O_2$max and $V_2$max, significant differences between smoker and non-smoker groups (p < 0.001). The recovery index was better in nonsmokers compared to cigarette smokers (p < 0.001) and in cigarette smokers versus hookah smokers (p < 0.01).

After the continuous training period, participants showed different improvements (Table 6). Significant changes in resting HR for the three groups NS, CS and HS were observed after training, with declines of -1.75 ± 2 bpm (P < 0.05), 2.5 ± 3.4 bpm (P < 0.01) and -2.2 ± 3.1 bpm (P < 0.05), respectively. Similarly, there was a decrease of SBP for both smoker groups (P < 0.05). In contrast, the decrease in DBP was significant only for the HS group (P < 0.01), by a decrease of -2.4 ± 3.4 (mm Hg).

The low-intensity continuous training induced also significant increases of $\dot{V}O_2$max for subjects of NS and CS groups and $O_2$max for the subjects of the CS and HS groups. Finally, the recovery index results showed most improved recoveries for the subjects of the three groups (NS: + 0.44 ± 0.4; CS: + 0.47 ± 0.6; HS: + 0 98 ± 0.8).

Discussion

Sedentary lifestyle, decline of lung function and low cardiorespiratory capacity are recognized as the main predictors of morbidity and mortality. Indeed, several studies have examined, using different protocols in different cases, the effect of exercise training on aerobic capacity and lung function. However, to our knowledge, no study has determined the effect of a continuous training program on these capacities among male adults unable or refuse to quit smoking. In fact, the aim of our study was to determine the contribution of 12-week low-intensity continuous training on lung function performance and aerobic fitness in cigarette and hookah smokers. Data of this study show the relationship between physical activity, cardiorespiratory capacity and lung function in healthy male, smokers and non-smokers.

The low-intensity continuous training was strongly associated with better values of the treadmill maximal exercise test. This finding was consistent with other studies. This study revealed considerable changes in O₂max and recovery index of all smoker participants. However, in the HS group, we found a greater improvement of two recorded values (see Fig. 1). In this context, Dausse et al. showed a significant increase in O₂max of the subjects who participated in a continuous training program for 8 weeks. Our findings support the results of MacDougall et al., Harmer et al., Macfarlane et al., Tijonna et al. and Daussin et al. who reported significant increases in O₂max values after various training programs. In contrast, a related study that was conducted by Mazoochi et al. showed no continuous training effect on O₂max. The results of this study can be confirmed by those of Denis et al.

![Fig 1. Improvement rate in percentage (Δ%) of cardiorespiratory parameters in Pre vs. Post program](figure1.png)
On the other hand, low-intensity continuous training induced a significant decrease in blood pressure and resting HR. The result is a significant reduction in SBP of -2% for CS group and -1.8% for the HS group, and only significant decrease of -2.5% of DBP in HS group (Fig.1). These favorable changes resulting from the continuous training on these two recorded values are in agreement with studies of Lawal & Kankanala\textsuperscript{45} and Laterza et al.\textsuperscript{46} and different from conclusions of Ferrier et al.\textsuperscript{47}. Similar results to our findings were reported by Westhoff et al.\textsuperscript{48}. Their findings show a significant decrease in SBP and DBP of -8.5 ± 8.2 mm Hg and -5.1 ± 3.7 mm Hg, respectively. This partial difference in results may be explained in part by the implemented protocols diversity (Training methods, protocol duration, participants’ age, smoking habits etc.) and the individual responses of each participant to exercise.

Exercise is an important component of pulmonary rehabilitation and may be associated with physiological and psychological benefits\textsuperscript{49}. Although the respiratory rehabilitation programs improve the quality of life and some physiological measures, the improvements in FEV\textsubscript{1} levels were not reported consistently\textsuperscript{2}. In our study, all participants, smokers and nonsmokers had higher levels of FEV\textsubscript{1} and FVC after this continuous training program. The improvement was about +2% and from +0.9% to +2%, respectively (Fig.2). Our results confirm the findings of Mehrotra et al.\textsuperscript{50}, who reported that lung function was better in most active subjects than sedentary subjects. However, there was no significant difference of FEV\textsubscript{1}/FVC in Pre vs. Post program. This is explained by the pulmonary efficiency weakness of our participants. These results are consistent with the findings of Cheng et al.\textsuperscript{51}.

The cigarette smoker participants who had the lowest FVC before training protocol, tended to have the best improvement among the three groups after training (≈ +2%). This may suggest that the respiratory system response to physical activity among CS group is higher than in HS or NS groups.

In summary, our analysis suggests that a low-intensity continuous training program was associated with an improved cardiorespiratory fitness and aspect of physiological wellness. This improvement was more marked in smokers than in nonsmokers, but the respiratory func-
tion change contributed little to this association for all participants after 12-weeks training.

Conclusion
The present study demonstrates that low-intensity continuous training improves cardiorespiratory fitness. Intensity and training volume have been closely monitored to demonstrate the continuous exercise importance in reducing lung function decline in cigarette and hookah smokers. Likewise, physical training with continuous exercises seems to be beneficial in hypertension prevention. Finally, these results could have important implications in prevention and treatment programs in both cigarette and hookah smokers unable or unwilling to quit.

Practical implications
- Smokers before training have a reduced lung function and worst cardiorespiratory fitness compared with no smokers.
- Significant improvements in FEV$_1$ and FEF50 % among smokers and nonsmokers after training.
- Significant improvements in FVC only in smokers
- Improvement in cardiorespiratory capacity is significantly higher in smokers than in nonsmokers.
- Smokers unable to quit smoking could focus at practicing leisure time physical activity regularly to reduce the decline of lung function and cardiorespiratory capacity.

Limitations of the study
The lack of a control group may be considered a limitation of the present study (smokers group follow the same daily activity during the same training period). I also think that future research should include a group of passive smokers. Likewise, the relatively small sample size could have limited our ability to detect group differences in the chosen parameters. This is indeed a limitation of this work, and should be considered relative to our findings.

Conflict of interest:
The authors declare that there is no conflict of interest regarding the publication of this article.

Source(s) of support: This research was supported by a grant from the laboratory of Pharmacology, Faculty of Medicine of Sfax, Tunisia.

Acknowledgement
The authors wish to express their sincere gratitude to all the participants who took part in this study for their maximal effort and cooperation. This study was conducted with the approval of the Research Ethics Committee of the faculty of medicine of Sfax, Tunisia.
