ABSTRACT

Chordoma is a rare, slow growing but locally aggressive malignant tumor derived from primitive notochordal elements, and it is usually found in the sacrococcygeal area. Chordomas are difficult to excise completely because preservation of sacral stability and sacral nerve pathways to the rectum and bladder limit the extent of surgery. The role of adjuvant treatment is uncertain and surgery remains the mainstay of its treatment. We present two such cases of sacral chordomas managed in our hospital. The clinical implications of these rare tumors are discussed.

Key Words: Chordoma, Sacrococcygeal

Chordomas are rare, slow growing but locally aggressive neoplasms derived from primitive notochordal elements. They are mainly found in the spheno-occipital and sacrococcygeal region.^[1] Although, metastasis is infrequent at presentation, the prognosis for patients with chordoma of sacrum is reported to be poor and attributable in most cases to intralesional resection. The value of adjuvant treatment is uncertain and resection remains the primary mode of treatment. Chordomas are difficult to excise completely because preservation of sacral stability and sacral nerve pathways to the rectum and bladder limit the extent of surgery.

CASE REPORTS

Case 1

A 45-year-old female was admitted with low backache of 9-month duration and tingling sensation to the left lower limb since 3 months, with no associated neurological deficits. Examination revealed a 10 cm x 5 cm swelling in the sacral region extending from the first sacral bone to the tip of the coccyx. On rectal examination, a firm to hard growth was palpable in the presacral plane, and the rectal mucosa was free. Mag-

netic resonance imaging (MRI) revealed a mass lesion involving the sacrum causing spinal canal and sacral foraminal compromise, more on the left side [Figure 1]. Radical resection of the tumor was done en bloc with S2 preservation, by posterior approach [Figure 2]. The patient developed urinary retention and peri-

neal sensory deficits postoperatively and was treated with antibiotics and steroids following which, there was complete recovery. After 6-month follow up, the patient has no evidence of loco-regional recurrence.

Case 2

A 43-year-old female presented with persistent low backache of 6-month duration and constipation. A routine rectal examination revealed a hard growth posteriorly with free rectal mucosa. Ultrasound and computer tomography (CT) scan confirmed the mass lesion involving the sacrum from S3 to the tip of the coccyx. She too underwent en bloc resection and had an uneventful recovery. The patient is on regular follow up.

DISCUSSION

Chordomas are neoplasms localized in the midline of the body with approximately 50% in the sacrococcygeal, 35% in the cervical spine and skull, and 15% in the thoracic spine and elsewhere. Male to female ratio is 3 : 1 and it is uncommon in individuals less than 40 years of age.

Although the biological behavior of the chordomas is highly variable, most conventional chordomas are slow growing.^[2] A sacral chordoma has presacral, subperiosteal extension, and also extension into the sacral canal. The sacrum and coccyx may be destroyed owing to tumor invasion. The rectum, bladder, uterus, and adnexae are either displaced or completely surrounded by the tumor. They are firm, grayish tumors, located and well encapsulated in soft tissue with variegat-

ed consistency and areas of hemorrhage. Metastases occur in only 10% of cases to lungs, liver, lymph nodes, skin, and muscles. Microscopically, it consists of pleomorphic cells in clusters amidst myxoid matrix. Immunohistochemically these cells are reactive to both cartilaginous and epithelial markers.^[3]

The presenting symptom in the most patients is local pain. About one-third of the patients also have radiculopathy due to irritation of the sciatic nerve or ileolumbar trunk.^[4] Radiological examinations show soft tissue mass in the presacral region with expansion of the sacrum and irregular areas of bone destruction, which are well observed on CT scan or MRI. Chordoma can be suspected if a midline sacrococcygeal tumor shows reduced uptake on bone scintigraphy with Tc-99m HMDP unlike most other bone tumors. Endorectal sonography can be used for diagnosis and guided biopsy.^[5] Small posterior incision or trocar biopsy is recommended. Transrectal or transvaginal biopsy violates the containing membranes of the presacral fascia and periosteum and should be avoided to prevent tumor seeding.^[9]

Definitive treatment is by wide resection with normal tissue margins and avoidance of spillage. Kaiser et al.^[6] reported that local recurrence rates correlated significantly with violation of tumor margins at initial surgery. En bloc sacral resection below the sacroiliac joint is a relatively straightforward procedure performed via a combined posterior-transperineal exposure. Tensionless wound closure may necessitate mobilization of soft tissue flaps but generally can be achieved without resorting to more elaborate reconstructive measures. In large tumors, a combined abdomino-sacral approach offers best results.^[7] Radical excision can be done with limited postoperative morbidity and preservation of neurological function, including sphincter control, provided that one S2 nerve root is left intact.^[8]

Postoperative irradiation is advocated but its efficacy is a subject of further debate. Samson et al.^[9] have advocated the use of radiotherapy to allow the surgeon to perform a marginal resection in case of high-sacral tumors allowing the preservation of nerve roots. Chemotherapy is of little value in these tumors.
