SUMMARY
The effect of exercise on circulating leucocytes with regards to changes in total and differential counts was studied in 25 adult Nigerians of both sexes. All subjects exercised on a bicycle ergometer till exhaustion. A significant (p<0.001) leucocytosis occurred immediately after the exercise with the predominant increase being lymphocytes. There was significant (p<0.01) eosinopenia and neutropenia in females. Basophilopenia was however significant (p<0.01) in the males but not in females. A significant (p<0.01) post-exercise monocytopenia was observed in the females but not in the males. This study demonstrates a marked leucocytosis due to lymphocytosis, and a decrease in the number of granulocytes and monocytes. The post-exercise lymphocytosis observed may be due to increased secretion of catecholamines, decreased adherence of leucocytes to the endothelium and massive influx of lymphocytes into the circulation from the lymphatic vessels.

RESUME
L’effet de l’exercice physique sur les globules blanc circulant dans le sang vis à vis de la variation de leur quantité totale et de leur pourcentage était étudié chez 25 adultes Nigerians des deux sexes. Tous les patients s’exerçaient sur une bicyclette ergonometrique jusqu’à l’épuisement. Un délicie significatif (P<0.001) en leucocytes affaraissait immédiatement après reduction en oesinophiles et neutrophiles chez les femmes. Une reduction significative (P<0.001) en basophiles et neutrophiles chez les Hommes mais pas chez les femmes. Une réduction significative (P<0.001) en monocytes était observée chez les femmes mais pas chez les Hommes. Cette étude démontre une réduction accentuée de globules blancs (leucocytes) due à la réduction des lymphocytes et une réduction du nombre de granulocytes et de monocytes. La réduction du nombre de globules blancs après l’exercice physique pourrait être due à l’augmentation en secretion de catecholamines et à la réduction d’adhérence des leucocytes à l’endothélium et à l’afflux massif des lymphocytes en circulation dans les vaisseaux lymphatiques.

The basal level of circulating white blood cells in man can be rapidly and substantially increased with physical activity (Andersen, 1955; Ahlborg, 1967; McCarthy et al., 1987). In most studies, it has been found that short term exercise (less than 30 minutes) leads to a lymphocytosis and a neutropenia (McCarthy and Dale, 1988); although there are a few reports of brief periods (usually less than five minutes) of very intense exercise causing an immediate decrease in leucocyte or neutrophil numbers, particularly in highly trained athletes (Andersen, 1955). The similar lymphocytosis which occurs early on during long term exercise has usually been found to subside later, leaving a predominant neutrophilia (see Garrey and Bryan, 1935). The reports in the literature have dealt mostly with the effect of exercise in Caucasians. Ezeilo (1972) reported some differences in the haematological values in Caucasians and Africans. This investigation assesses the comparative effect of a brief, severe muscular exercise in an African (Nigerian) population.

MATERIALS AND METHODS
Twenty-five students of the University of Maiduguri volunteered for this study. Their ages ranged from 17 to 28 years, with a mean of 22.5 ± 3.4 years. All were physically inactive, i. e., had no formal exercise programme for 12 months. Apart from absence of symptoms, pregnancy or current medication, physical fitness and apparent good health constituted the criteria for inclusion in the study. Each student volunteered with informed consent to participate in the exercise.

Experimental protocol
The experiments were conducted under laboratory conditions, temperature ranging from 34EC to 36EC. Each subject exercised to exhaustion on a bicycle ergometer at a work load maintained at 1.5 kg for the males and 1.0 kg for the females. Exhaustion was defined as the inability to maintain the required pedal frequency.

Following Andersen (1955) the subjects came to the laboratory in a post-absorptive state on the testing day. After resting at least 20 minutes, pre-exercise blood (2.5 ml) was drawn from a cubital vein with minimum of stasis. Immediately after exercise, a blood sample was drawn in a similar way.

White blood cell count and differential leucocyte counts were performed for each subject before and after exercise using the method described by Moore (1958).

**Statistical analysis**

Except where indicated, results are presented as means ± standard errors of means. Differences between means were assessed using paired Student's t-tests.

**RESULTS**

The post-exercise total leucocyte counts showed a significant (p<0.01) increase over the pre-exercise values in all subjects (Table 1). In the females, the percentage increase averaged 32.4% as against 22.8% in males. The percentage increase in total leucocyte count immediately after the exercise in all subjects averaged 26.1% (Table 1). The pre-exercise total leucocyte count in males was significantly (p<0.01) higher than in females (Table 1).

*Statistical levels of significance were determined using Student's t-test. *Not significant.

Neutropenia at significant levels was observed (Table 2) immediately after the exercise in females (p<0.01), in the pooled category (p<0.01) but not in the males (p<0.01). There was marked eosinopenia in all subjects after the exercise (Table 2). A significant (p<0.001) lymphocytosis also occurred immediately after the exercise (Table 2). The differential lymphocyte count significantly appreciated from 54.0 ± 4.4 to 72.0 ± 2.3 in females (p<0.001); 64.0 ± 2.2 to 77.0 ± 2.9 in males (p<0.001) and in the pooled category from 60.0 ± 2.4 to 75.0 ± 2.0 (p<0.001). Basophilopenia was significantly (p<0.01) observed in the males (Table 2). However, monocytopenia significantly
occurred (p<0.01) in females and in the pooled category only (Table 2).

DISCUSSION

It has been shown that active participation in a short bout of muscular exercise caused marked leucocytosis with the predominant increase being lymphocytes (Tables 1 and 2). This relates to the findings of Andersen (1955), Masuhara et al. (1987) and Sodique (1997) that short bouts of physical exercise on a bicycle ergometer massively increased leucocyte counts in both trained and untrained athletes.

The leucocytosis caused by exercise in this study could be due to a number of factors. These would include the actions of catecholamines, cortisol, demargination, neuronal transmitters and peptides or purine chemical transmitters (see McCarthy and Dale, 1988). A possible explanation for the post-exercise increase in leucocyte count is that large numbers of cells which at rest, are adherent to the walls of blood vessels (endothelium), i.e., marginalized pool, are suddenly washed into circulation (Morehouse and Miller, 1976). This is called demargination and results in massive increase in the number of leucocytes in the circulating pool. The demargination is due to the force of increased volume and velocity of blood flow (Morehouse and Miller, 1976). Demargination could also be due to the effects of stress hormones, such as adrenaline, which decreases the adherence of leucocytes to the endothelium via interaction with $\beta$-receptors on both cell types (Gleeson, 1995).

In brief exercise (<1 hour), as in this study, only the effects of catecholamines in increasing the ratio of circulating to non-circulating cells, as well as that of demargination will be evident (McCarthy and Dale, 1988). The effect of cortisol can only be observed much later as a delayed increase in the total number of leucocytes in the vascular compartment (Keast et al., 1988). Catecholamines have indeed been shown to modify both the number and function of circulating lymphocytes (Keast et al., 1988). Some of the effects of adrenaline on the sub-populations of circulating leucocyte, may be sequential in nature, with a predominant and immediate rise in lymphocytes (Keast et al., 1988) as seen in this study (Table 2), followed by a neutrophilia after about 30 minutes (Keast et al., 1988). It has been suggested that the lymphocytosis, due to the action of adrenaline, may result from increased emptying of lymph into the blood stream through the thoracic duct (Keast et al., 1988).

Stress of any sort (including exercise, as in the present study) results in an increased secretion of hormones of the adrenal cortex and one of the results produced by the actions of these hormones is a decrease in the number of eosinophils in the blood (Morehouse and Miller, 1976). As the exercise undergone in this study, however, was brief, the eosinopenia observed is unlikely to be essentially due to the effect of the hormones of the adrenal cortex - specifically cortisol, which are released over a longer duration of exercise, but rather a relative decrease due to the marked lymphocytosis. This explanation may also be applicable to the observed basophilia and monocytopenia. Both basophilia and monocytopenia are normal physiological effects of cortisol on white blood cells (McCarthy and Dale, 1988), but in this study, are probably relative decreases due to the marked lymphocytosis.

The neutropenia observed was dependent on the severity and duration of the exercise. Because the exercise was hard and vigorous, the active muscles (skeletal) underwent anaerobic respiration. This resulted in the accumulation of lactic acid in the muscles. Lactic acid in the muscles irritates them and acts as a stimulus similar to inflammation. As neutrophils are the first line of defence (Guyton, 1991), they leave the vascular compartment by diapedesis and move into the tissues, in the direction of the source of the stimulus by chemotaxis. This accounts for the neutropenia observed.

Leucocytosis due to exercise occurring in males and females was not significantly different (Tables 1 and 2). This lends weight to the statement that 'femaleness' and 'maleness', in relation to exercise seem to be more of a matter of morphology than physiology (Morehouse and Miller, 1976).
