Aspergillus sellar abscess is a very rare form of fungal infections of the central nervous system (CNS). In this report, we describe the successful treatment of a patient with aspergillus sellar abscess. A 65-year-old woman presented with headache, nasal discharge and decreased visual acuity. The diagnosis of sellar mass was made on the basis of magnetic resonance imaging (MRI) examination. The computed tomography (CT) scan revealed sellar enlargement and sellar floor bony destruction. After hospitalization the patient underwent transsphenoidal surgery. Histopathological examination of the sellar mass revealed aspergillosis. Postoperatively, amphotericine-B and itraconazole therapy was started. During a six-month follow-up, the patient's headache and inertia disappeared, visual acuity improved. Aspergillus sellar abscess must be considered in the differential diagnosis of a sellar mass. The correct diagnosis of pituitary aspergillosis can only be achieved by histopathological examination. Surgical intervention and antifungal therapy should be considered the optimal treatment.

Key words: Amphotericine-B, aspergillus, sellar abscess, transsphenoidal surgery

Case Report

A 65-year-old woman was admitted to our hospital with five months of headache, nasal discharge, two months of decreased visual acuity, with a deteriorating condition for a week. She complained of bilateral frontal-temporal drill pain, and inertia. The diagnosis of sellar mass was made on the basis of MRI examination. Her medical history was insignificant for diabetes, malignancies, drug abuse, blood transfusions, meningitis and head trauma. Physical examination was normal and the patient was afebrile. The neurological examination revealed bilateral papilledema and bitemporal hemianopsia and impairment of visual acuity. The MRI revealed a sellar suprasellar mass with a dimension of 2.5 cm×2.5 cm×2.5 cm, iso-intense on T1-weighted images with peripheral hyperdensity. On T2-weighted images the central part of the mass was hyperintense although peripheral iso-intensity was present. Contrast enhanced MRI examination also showed that the sellar mass had a peripheral contrast enhanced rim [Figures 1, 2]. The computed tomography (CT) scan revealed sellar enlargement and sellar floor bony destruction.

Aspergillus sellar abscess is a very rare form of fungal infections of the central nervous system (CNS). Figure 1: Preoperative gadolinium enhanced T1-weighted MRI coronal scan showing sellar suprasellar mass with peripheral contrast enhancement
Endocrinological tests showed depressed levels of adrenocorticotropic hormone (ACTH), growth hormone (GH), prolactine (PRL), thyrotropic-stimulating hormone (TSH), gonadotrophines. After hospitalization the patient underwent transsphenoidal surgery. When the sphenoid sinus was opened, the mucosa, which cultured optimally on Sabourad’s agar demonstrating characteristic conidiophores, was found to be thickened and purulent material was seen, and blood and cerebrospinal fluid cultures negative. The sellar floor bony was eroded. A necrotic sellar mass was removed through the microscope. The diaphragma sellae was intact and not opened. The sellar cavity and sphenoid sinus were irrigated with gentamycine solution. At the end of the operation we aerated the infected sphenoid sinus. Histopathological examination of the sellar mass resulted in the diagnosis of aspergillosis. After the operation, amphotericine-B(25 mg/d) and itraconazole(800 mg/d) therapy was started. During a 6-month follow-up, the patient’s headache and inertia disappeared, visual acuity improved.

**Discussion**

Aspergillus is a fungal organism which has lots of species and a few of them are pathogenic. Aspergilli are opportunistic pathogens which are ubiquitous fungi found in soil and organic materials and can establish saprophytic growth within the respiratory tract after inhalation. The organism can become pathogenic under immune suppression, granulocytopenia, diabetes mellitus or prolonged hospitalization. Central nervous system (CNS) aspergillosis presents as meningitis, encephalitis, brain abscesses, subdural abscesses, mycotic arteritis or sellar abscess. Aspergillus can reach the CNS by three different routes. The first is by hematogenous spread from a remote extracranial focus, usually the lung. The second is by extension from a contiguous extracranial location which is often the paranasal sinus or the nasal cavity. The third is direct introduction of aspergillus by a neurosurgical procedure iatrogenically. In our case, the patient presented with nasal cavity and sphenoid sinus infection inflammation, the CT scan showed sellar floor bony destruction, therefore, aspergillus infection probably spread from the nasal sinus.

Diagnosis of CNS aspergillosis is difficult because the presenting symptoms in these patients are extremely identical to the symptoms in patients with pituitary adenomas. Headaches, visual disturbances and endocrine failure are the common symptoms and signs. On CT usually sellar enlargement and a low-density sellar mass with contrast enhanced rim is seen. Magnetic resonance imaging is the best examination in the radiological evaluation of a sellar abscess. A sellar abscess usually appears as a hypo-isointense sellar mass on T1-weighted sequences and as a hyperintense mass on T2-weighted sequences. A peripheral contrast enhancing rim is usually present. In our case, plain MRI findings suggested a pituitary adenoma, although contrast enhanced rim of the mass and nasal cavity infection findings led us to the preoperative diagnosis of sellar abscess.

However, in our case the diagnosis of sellar aspergillosis was made as a result of histopathological examination because clinical and radiological findings were not specific.

The treatment of the sellar abscess is surgical resection via a transsphenoidal approach, and a craniotomy increases the risk of contaminating subarachnoid spaces and causing meningo-encephalitis. Transsphenoidal approach is also dangerous because it is absolutely close to the border of the subarachnoid space. We must rigorously avoid even microtraumas of the diaphragma sellae and keep it intact, because of...
the risk of a subarachnoid spread with aspergillus, such infections are lethal in most cases. In the nasal respectively sphenoid phase, at the end of the operation the neurosurgeon has to aerate the infected sphenoid sinus because a closure of the situs leads to a recurrent infection. Antibiotic treatment alone is not enough to save the infected region and to prevent a re-infection. Immediately after the histopathological diagnosis, the patients with aspergillus sellar abscess must be treated intravenously with amphotericine-B or combined therapy with amphotericine-B and flucytosine or itraconazole. In India, Kshirsagar et al had developed liposomal amphotericin, to patient-worthy, sterile pyrogen free preparations. The same group studied different dosage regimens of liposomal amphotericin in Aspergillus model and found that liposomal amphotericin was more effective than equal dose of free amphotericin-B. Subsequent clinical trials with Indian liposomal amphotericin-B (Fungisome™) have demonstrated its safety and efficacy in the treatment of CNS aspergillosis. In focal CNS aspergillosis total cure can be achieved in approximately 30% of the cases by surgical resection and intensive antifungal therapy. In conclusion, aspergillus sellar abscess should be considered in the differential diagnosis of a pituitary mass. The correct diagnosis of sellar aspergillosis can only be achieved by histopathological examination of tissue obtained at surgery. The optimal treatment is a combination of surgical resection and intensive antifungal therapy.
